ABSTRACT

A common bioassay problem in applied ecology is to estimate values of an environmental variable from species incidence or abundance data. An example is the problem of reconstructing past changes in acidity (pH) in lakes from diatom assemblages found in successive strata of the bottom sediment. The method of weighted averaging is based on indicator values, the indicator value of a species being, intuitively, the value of the environmental variable most preferred by that species. Indicator values of all species present in a site are averaged to give an estimate of the value of the environmental variable at the site. The average is weighted by species abundances, if known, with absent species having zero weight. Using field data, several authors have compiled lists of indicator values of species for various environmental variables for use in weighted averaging, e.g. pH indicator values of diatom species. In this paper the properties of the method of weighted averaging are studied, starting from the idea that indicator values are parameters of response curves that describe the expected abundance of each species in relation to the environmental variable. In practice the response curves must be estimated by regression methods, but here they are assumed to be known in advance. Conditions are derived under which the weighted average is a consistent and efficient estimator for the value of an environmental variable at a site. Because weighted averaging is central to the ordination technique known as reciprocal averaging or correspondence analysis, the conditions also define models that are implicitly invoked when reciprocal averaging is used in ecological ordination studies.

1. INTRODUCTION

Plant species need particular environmental conditions for regeneration, establishment, and growth. It should therefore be possible to infer the environmental conditions at a site from the species that occur there. This type of bioassay has become popular [3, 6, 9, 19] with the publication of lists of indicator values of species with respect to various environmental variables. For example, Ellenberg [8] has published indicator values of Central European
plants with respect to site variables including soil moisture, pH, and nitrogen level. Ellenberg based the indicator values on his field observations of the conditions under which particular species occurred and, to a lesser extent, on laboratory experiments. For example, a plant species may prefer a particular soil moisture content, and not grow at all in places where the soil is either too dry and too wet. Intuitively, the indicator value is then the value most preferred by a species (cf. Figure 1). Ellenberg [8] did not give a precise definition of “indicator value.” However, Ellenberg [7, 8] did describe a method to predict the value of an environmental variable: the method consists simply of averaging indicator values for the plant species that are present. For quantitative data, the average is weighted by species abundance, with absent species carrying zero weight. This method has been applied to vascular plants [12, 17, 21, 23, 25], to diatoms [20], and to aquatic organisms and the biological evaluation of water quality [19].

It might be thought easier to measure environmental variables at a site than to infer their values from the species that grow there. But often it is not. For example, total values over time may be required; repeated measurements are costly, while plants automatically integrate environmental conditions over time. This is one of the ideas behind biological evaluation of water quality and biomonitoring in general. There are also situations where it is impossible to measure environmental variables by direct means, whereas a biological record does exist. An example is the reconstruction of past changes in acidity (pH) in lakes, from diatom assemblages found in successive strata of the bottom sediment; this technique is an important tool in acid rain research. Most researchers in this area use the indicator values for acidity of diatom species as compiled by Hustedt in the 1930s [2]. A more sophisticated
method, yet to be implemented, is to build firstly a (nonlinear) regression model from data on species occurrences and present pH in lakes, which yields for each species an estimated response curve for the probability of occurrence versus pH; and secondly to use these response curves for the calibration of pH from species data, for example by maximum likelihood estimation. Here the indicator value of a species is just a parameter of the response curve of that species, the mode of the curve being one possible definition of the indicator value.

In this paper we study the properties of weighted averaging of indicator values to estimate the value of a continuous environmental variable at a site. We do this by seeking conditions under which weighted averaging compares favorably with methods based on explicit response curves. We use assumptions (Section 2) that idealize the real world, among others that a single environmental variable determines the species composition at a site and that the response curves of the species with respect to this variable are already known. Certainly, weighted averaging is of little value if it has undesirable properties under ideal assumptions. On the other hand, there is no advantage in using an elaborate technique if a simpler one would be equally good. We answer two questions:

(1) How should indicator values of species be defined in terms of response curves to ensure that the weighted average is a consistent estimator? (The weighted average is called consistent if it converges in probability to the true value of the environmental variable as the number of species available increases.)

(2) What should the response curves look like to ensure that the weighted average is an efficient estimator? (An estimator is called efficient if its mean squared error is minimum.)

2. WEIGHTED AVERAGING AND RESPONSE CURVES: DEFINITIONS

Let $x$ denote a quantitative environmental variable, and $x_0$ the value of this variable at a particular site. We want to estimate this value $x_0$ by checking which species (out of a large number) are present at that site or, more generally, the abundance of each species. Let $Y_k$ be the abundance ($Y_k \geq 0$) of the $k$th species ($k = 1, 2, 3, \ldots$), and let $u_k$ be its indicator value, usually taken from a published list of indicator values. To estimate $x_0$, ecologists commonly use the weighted average [7–9]

$$\hat{x}_{WA} = \frac{\sum_k Y_k u_k}{\sum_k Y_k},$$  \hspace{1cm} (2.1)
where summations are over all species. To make sense, \( \hat{x}_{WA} \) and hence the values for \( u_k \) must have the same dimension as \( x \). The indicator values are therefore location parameters on \( x \).

To be a potential indicator, a species must show a distinct relation to the indicated environmental variable \( x \). We define the relations between species and the environmental variable by a statistical response model with a response curve \( \mu_k(x) \), a known function of \( x \), for each species \( k \). \( \mu_k(x_0) \) specifies the expectation of the value \( Y_k \) observed at the site with value \( x_0 \) for \( x \). The observational data will be assumed to be independent random variables with variances depending on the expectations only. The variance of \( Y_k \) is therefore a known function \( v_k(x_0) = v^*(\mu_k(x)) \). For presence-absence data \( Y_k \) is a Bernoulli variable and \( \mu_k(x_0) \) is the probability that the \( k \)th species is present at a site with \( x = x_0 \). Then \( v^*(\mu) = \mu(1 - \mu) \). For counts, the data may be assumed to have a Poisson distribution so that \( v^*(\mu) = \mu \), whereas for continuous quantitative data with constant coefficient of variation \( v^*(\mu) = c\mu^2 \) the data could have a Gamma distribution.

We consider response curves that form a location family, i.e. have identical (but arbitrary) shape and different positions along the real line. Formally, \( \mu_k(x) = \mu(x - u_k) \) for some function \( \mu(\cdot) \) that is almost everywhere continuous, and with location parameters for which we take the indicator values \( \{ u_k \} \). It follows that \( v_k(x) = v(x - u_k) \), where \( v(\cdot) \) is the variance function corresponding to \( \mu(\cdot) \). We use asymptotics in which the number of species available for the estimation of \( x_0 \) increases indefinitely in such a way that the indicator values become increasingly densely spaced on every finite interval.

3. CONSISTENCY AND THE DEFINITION OF INDICATOR VALUE

Whether the weighted average is a "good" estimator depends on (1) the shape of the response curves, (2) the definition of indicator value, and (3) the distribution of the indicator values along the environmental variable. In this section we reverse the reasoning: we require that the weighted average be a consistent estimator of \( x_0 \), and from that requirement we derive conditions on the response curves, a definition of indicator value, and conditions on the distribution of the indicator values.

We express the number of indicator values at the point \( x \) by \( \lambda[H_{\lambda}(x) - H_{\lambda}(x - 0)] \), where \( \lambda \) is the average number of indicator values per unit length, \( H_{\lambda}(x) = \lim_{y \to x} H_{\lambda}(y) \), and \( H_{\lambda}(\cdot) \) is a nondecreasing right-continuous stepfunction [in the terminology of measure theory, \( H_{\lambda}(\cdot) \) is the distribution function of a discrete measure]. We suppose that for \( \lambda \to \infty \) \( H_{\lambda}(\cdot) \) converges to a distribution function with bounded and continuous derivative \( h(\cdot) \). \( h(\cdot) \) is the limiting density function of the indicator values. Now, \( \hat{x}_{WA} = T/R \), where \( T = \lambda^{-1}\sum_k Y_k u_k \) and \( R = \lambda^{-1}\sum_k Y_k \). It follows that \( T \) has expectation \( \lambda^{-1}\sum_k u_k \mu(x_0 - u_k) = \int u \mu(x_0 - u) dH_{\lambda}(u) \), which for
WEIGHTED AVERAGING OF INDICATOR VALUES

large \( \lambda \) approaches

\[
\int u\mu(x_0 - u)h(u)\,du = x_0\int \mu(u)h(x_0 - u)\,du - \int u\mu(u)h(x_0 - u)\,du
\]  

(3.1)

Moreover, \( \text{var}(T) \rightarrow 0 \) \((\lambda \rightarrow \infty)\) if and only if \( \int x^2v(x)\,dx \) exists; then \( T \) converges in probability to (3.1). Similarly, \( R = \lambda^{-1}\sum_k Y_k \) converges in probability to \( \int \mu(u)h(x_0 - u)\,du > 0 \). Therefore \( T/R \) converges to \( x_0 \) if and only if \( \int u\mu(u)h(x_0 - u)\,du = 0 \). The latter condition should hold for every value of \( x_0 \); this condition may be fulfilled if the function \( h(x) \) is constant, i.e. if the indicator values are evenly distributed. For particular \( \mu(\cdot) \), certain almost periodic functions \( h(\cdot) \) might do as well, but we believe these functions to be of no practical importance. For some \( \mu(\cdot) \), e.g. the Gaussian curve [1, 9], constant \( h(\cdot) \) is a necessary condition. If \( h(x) = c \), we get \( \int u\mu(u)\,du = 0 \): the centroid of \( \mu(\cdot) \) must be equal to zero. Consequently, the centroid of \( \mu_k(x) = \mu(x - u_k) \) must be equal to \( u_k \), or rephrasing, the indicator values must be the centroids of their response curves,

\[
u_k = \frac{\int x\mu_k(x)\,dx}{\int \mu_k(x)\,dx}
\]  

(3.2)

This definition of indicator value is necessary for the weighted average to be consistent. Note that defined in this way, the indicator value of a unimodal response curve is only equal to the most preferred value (mode or optimum) if the curve is symmetric. Note also that we had to assume in the derivation that both integrals in (3.2), and \( \int x^2v(x)\,dx \), exist. The weighted average is inconsistent for response curves that do not satisfy these conditions, e.g. monotone increasing or decreasing functions. The weighted average is also inconsistent for data with a constant variance function.

In conclusion, the weighted average is a consistent estimator of \( x_0 \) (for \( \lambda \rightarrow \infty \)) provided (1) the three aforementioned conditions on integrals of the response and variance curve hold, (2) the indicator values are centroids of the response curves, and (3) the indicator values are evenly distributed along the real line. Using central limit theorems and laws of large numbers valid for independent but nonidentically distributed random quantities [5], it follows that the weighted average is then asymptotically normal with variance [11, Equation (10.17), p. 247]

\[
\nu_{WA} = \frac{\sum_k (u_k - x_0)^2 v_k(x_0)}{\left[\sum_k \mu_k(x_0)\right]^2}.
\]  

(3.3)
4. THE MAXIMUM LIKELIHOOD APPROACH

When response curves can be expressed in parametric form, $x_0$ can be estimated by the method of maximum likelihood [4]. Maximum likelihood estimators are often good estimators in large samples: under mild conditions they are consistent and asymptotically normal with minimal variance [4, 5]. These assertions hold for our applications; the proof thereof goes along similar lines as in the standard case of independent and identically distributed random variables. Maximum likelihood is more widely applicable than weighted averaging.

For Bernoulli, Poisson, or Gamma random variables the maximum likelihood estimator is the solution for $x_0$ of the maximum likelihood equation [14]

$$\frac{\delta \log L}{\delta x_0} = \sum_k \frac{\mu'_k(x_0)(Y_k - \mu_k(x_0))}{\nu_k(x_0)} = 0,$$

(4.1)

where $\mu'_k(x_0)$ denotes the derivative of $\mu_k(x)$ with respect to $x$, evaluated at $x_0$. Often the solution of (4.1) can only be obtained by numerical methods. The asymptotic variance of the maximum likelihood estimator is, as usual, the inverse of the information [4] and equals

$$\nu_{ML} = \left[ \sum_k \left( \frac{\mu'_k(x_0)}{\nu_k(x_0)} \right)^2 \right]^{-1}.$$  

(4.2)

When the distribution of $Y_k$ is not fully specified, Equation (4.1) is a quasi-likelihood equation, which often gives estimators with good asymptotic properties [14]. This extension of (4.1) and (4.2) is important when count data are overdispersed with variance proportional to the mean.

5. EFFICIENCY AND SHAPE

For large numbers of species maximum likelihood will in general be more efficient than weighted averaging, but the latter method is much easier to use. It is therefore of interest to investigate whether there exists a shape of the response curves for which weighted averaging achieves, in terms of mean squared error, asymptotically unit efficiency with respect to maximum likelihood. With the species packing model [13, 22] in view, we adopt the location family of Section 2 with equispaced indicator values. In this situation both methods are consistent. It is therefore sufficient to compare the variances (3.3) and (4.2) for spacing $d \to 0$. It is proved in the Appendix that, asymptotically, $\nu_{ML} \leq \nu_{WA}$ with equality if and only if

$$\mu'_k(x) = -\frac{(x - u_k) v_k(x)}{t^2},$$

(5.1)
for \( t \) a nonzero constant. The differential equation (5.1) has a solution of the form

\[
f(\mu_k(x)) = a - \frac{1}{2} \frac{(x - u_k)^2}{t^2},
\]

(5.2)

where the function \( f(\cdot) \) depends on the variance function. The curves in (5.2) form a generalized linear model [14, 16], and the function \( f(\cdot) \) is precisely the "natural" link function of such a model: the logistic function \( f(\mu) = \log[\mu/(1 - \mu)] \) for Bernoulli variables, the logarithmic function \( f(\mu) = \log \mu \) for Poisson variables, and the inverse function \( f(\mu) = -1/\mu \) (and \( a < 0 \)) for Gamma variables. In (5.2) the parameter \( a \) is the maximum of \( f(\cdot) \) attained at the indicator value, mode, or optimum \( u_k \), and \( t \), termed the tolerance, is a measure of curve width. For Poisson variables (5.2) is precisely the Gaussian response curve that is frequently invoked in plant ecological studies [1, 9].

For presence-absence data we propose to term (5.2) the Gaussian logit response curve (Figure 1). Its formula is

\[
\mu_k(x) = \frac{\exp\left\{ a - \frac{1}{2} \frac{(x - u_k)^2}{t^2} \right\}}{1 + \exp\left\{ a - \frac{1}{2} \frac{(x - u_k)^2}{t^2} \right\}}.
\]

(5.3)

Instead of \( a \) we may use the parameter \( p_{\text{max}} = 1/(1 + e^{-a}) \), the maximum probability of occurrence. If \( p_{\text{max}} \to 0 \), \( \mu_k(x) \) approaches the Gaussian curve. Thus for many rare species, the two models are effectively the same. Using (3.3) and (4.2), we found numerically that for Bernoulli variables and Gaussian rather than Gaussian logit curves, the efficiency \((v_{\text{ML}}/v_{\text{WA}})\) of weighted averaging decreased from 1.0 to 0.8 when \( p_{\text{max}} \) was increased from near zero to 0.9.

The maximum likelihood variance (4.2) can be simplified by substitution of (5.1), which gives

\[
v_{\text{ML}} = t^4 \left[ \sum_k (u_k - x_0)^2 v_k(x_0) \right]^{-1},
\]

(5.4)

Because of the equal spacing of the indicator values,

\[
\sum_k (u_k - x_0)^2 v_k(x_0) \approx t^2 \sum_k \mu_k(x_0).
\]

(5.5)

For integrals the approximation (5.5) is an equality, as follows from (5.1) and integration by parts. Numerical calculations showed that the approximation in (5.5) is quite good, provided the indicator values are equispaced on a "large" interval \( I \) around \( x_0 \) with spacing less than \( t \), where \( I = \)
\{ u \mid \mu(x_0 - u) > \delta, \ u \in \mathbb{R} \} \text{ for small } \delta. \text{ With (5.5) we obtain }

\[ u_{\text{ML}} \approx \frac{t^2}{\sum_k \mu_k(x_0)}. \quad (5.6) \]

Substitution of (5.5) in (3.3) gives the same result for \( v_{\text{WA}} \). A sample-based version of (5.6) is \( t^2/\sum_k Y_k \).

We carried out a simulation study in which presence-absence data were generated according to the model (5.3) with \( t = 1 \), equispaced optima (\( d \leq 1 \): \( d = 1, 0.5, 0.25, 0.12, 0.06, \text{ or } 0.03 \)) on the interval \((-5, 5)\) and maximum probability either .1 or .5 or .9. The minimum number of species was therefore 10. \( x_0 \) was always chosen close to the center of the interval, between 0 and \( d/2 \). The simulations were constrained to give at least two species occurrences per sample. In each case 1000 samples were generated. For each sample \( x_0 \) was estimated by weighted averaging and by maximum likelihood. All cases showed an efficiency in terms of mean squared error of 1.00, even when only 10 species were positioned on the interval. In most cases the mean squared error of both \( \hat{x}_{\text{WA}} \) and \( \hat{x}_{\text{ML}} \) exceeded the theoretical variance (5.6), but the excess was less than 12% when the average number of species occurrences per sample was larger than 5.

6. VARYING SPACING, MAXIMA, AND TOLERANCES

For the "optimal" response curves (5.2) the weighted average still has asymptotically unit efficiency when the species can be divided into sets such that within each set the species have equal maxima and equispaced optima with spacing less than \( t \) (Figure 1). An important example arises when the species are divided into sets on the basis of their response to another environmental variable. The result follows from (5.5): for each set of species (5.5) holds and can be substituted for each set in (3.3) and (5.4), which leads to (5.6) in both cases. However, this trick does not carry through when the tolerance varies between species, because substitution of (5.5) now involves different tolerances for different sets. As a result the efficiency can drop considerably when the tolerance varies. For example, with two tolerances differing by a factor of two, the efficiency drops to ca. 0.6 in the logistic model with maximum probability of occurrence .5. Full efficiency can then be retained by using a tolerance-weighted version of the weighted average,

\[ \hat{x}_{\text{WAT}} = \sum_k \frac{Y_k u_k}{\sum_k \frac{Y_k}{t_k^2}}. \quad (6.1) \]

In (6.1) good indicator species get more weight than bad ones, an intuitively
reasonable idea used already by Zelinka and Marvan [24]. The results of this section suggest that equality of tolerances is a more critical assumption in the weighted average (2.1) than equality of maxima and equal spacing.

7. RANDOM INDICATOR VALUES AND RANDOM RESPONSE CURVES

The shapes of response curves may vary between species. In this section we mimic this variability by assuming that response curves arise from a "superpopulation" model consisting of three parts:

1. A Poisson point process $P$ that generates indicator values $\{u_k\}$ on the real line with intensity function $\lambda h(x)$ [$\lambda > 0$ and $h(x) > 0$ for every $x$].
2. A stochastic process $S$ that generates shapes $M(x)$ for response curves, independently for any indicator value $u_k$ generated by $P$. Any realization of $M(x)$ is a bounded, nonnegative continuous function on the real line such that $x^2M(x)$ and $x^2V(x) \in L^1(-\infty, \infty)$, where $V(\cdot)$ is the variance function corresponding to $M(\cdot)$, and $\int xM(x) \, dx = 0$. Expectation and variance with respect to $S$ are denoted by $E_S$ and $\text{var}_S$.
3. A translation of $M(x)$ over $u_k$: $M(x) = M(x-u_k)$.

The model will be termed the translation model. It is proved in the Appendix that the weighted average is consistent (as $\lambda \to \infty$) if $h(x) = 1$. Then $P$ is a homogeneous Poisson process, and the indicator values are said to be randomly spaced. The asymptotic variances are then

\[
v_{\text{WA}} = \frac{\int \int (u-x_0)^2 E_S \{V(u) + M^2(u)\} \, du}{\lambda \left[ \int E_S M(u) \, du \right]^2} \tag{7.1}\]

and

\[
v_{\text{ML}} = \left[ \int E_S \left( \frac{[M'(u)]^2}{V(u)} \right) \, du \right]^{-1} \tag{7.2}\]

respectively. $v_{\text{WA}}$ is always strictly greater than $v_{\text{ML}}$. For the response curves (5.2) (process $S$ degenerate) and random spacing, the efficiency of weighted averaging increases to unity when the maximum of $\mu(\cdot)$ decreases to 0, as shown in Figure 2 for logistic $f(\cdot)$. To obtain the variances in the case of equal instead of random spacing between the indicator values, $M^2(u)$ in (7.1) must be replaced by $\text{var}_S \{M(u)\}$, whereas (7.2) remains the same. In this case $v_{\text{ML}} \leq v_{\text{WA}}$ with equality if and only if the response curves are nonrandom and satisfy (5.2).
FIG. 2. The efficiency of weighted averaging with respect to maximum likelihood against the maximum probability of occurrence \(P_{\text{max}}\) for Gaussian logit curves with randomly spaced optima and equal maxima and tolerances [\(\text{eff} = \epsilon_{\text{ML}}/\epsilon_{\text{WA}} = (1/\tau)^2\)].

To simplify (7.1) for Bernoulli variables we define the commonness \(\alpha\) and the standard deviation \(\tau\) of the expected response curve \(\mu(x) = E_s\{M(x)\}\) by

\[
\alpha = \int \mu(x) \, dx \quad \text{and} \quad \tau^2 = \frac{\int x^2 \mu(x) \, dx}{\alpha} \quad (7.3)
\]

From (7.1) we obtain [cf. (5.6)]

\[
\nu_{\text{WA}} = \frac{\tau^2}{\lambda \alpha}. \quad (7.4)
\]

An unbiased estimator for (7.4) is the usual sample variance of the mean of the indicator values of the species present at the site. It is only in this special case that the indicator values might be considered as independent "samples" from a probability distribution.
Simulations, as in Section 5, with Gaussian logit curves (5.3), but with random, instead of equispaced, optima showed calculated efficiencies that agreed with the asymptotic efficiencies shown in Figure 2. The mean squared errors exceeded the theoretical variances (5.6) and (7.4), the convergence to the theoretical variances being slower than in Section 5. For random optima the excess was less than about 15% when the average number of species occurrences per sample was larger than 10.

8. DISCUSSION

This paper shows that a method proposed and used by community ecologists, namely weighted averaging, performs well under a model advocated by evolutionary ecologists, namely the species packing model [13]. This model is based on the idea that competing species evolve to occupy maximally separated niches with respect to a limiting resource. This idea applies as well to the occurrence of competing species along habitat variables [22]. Response curves should therefore have minimal overlap; hence, equally spaced indicator values. It should be noted that our asymptotic theory ignores another consequence of this model, namely that there exists a limiting similarity beyond which competing species cannot coexist. The minimal spacing derived by MacArthur and Levins [13] is about equal to the standard deviation of the response curves. But direct gradient analyses often show much closer spacings than that [9, 22]. Moreover, in lists of indicator values such as Ellenberg [8], the values coincide for many species. Of course, many species are coexisting without seriously competing.

Our results suggest that the distribution of the indicator values along the indicated variable should be even. But for Ellenberg’s [8] list with about 2000 plant species the indicator values show uneven and markedly skew distributions [6, Figure 11]. A change of scale of the environmental variables could alleviate this problem. However, such a change modifies the response curves as well as their centroids. If the indicator values are centroids on the present scale, a nonlinear change of scale would destroy this desirable property. An alternative estimator is obtained by replacing $Y_k$ with $Y_k/h(u_k)$ in (2.1). This estimator can be shown to be consistent under the model of Section 7. However, when the species packing model does hold in a part, say $A$, of a multidimensional habitat space, possibly uneven marginal distributions of indicator values do not destroy the attractive properties of the usual weighted average (2.1). More specifically, when the indicator values are regularly spaced and the value $x_0$ of the site lies well within $A$ (i.e., there is a subset $B$ of $A$ such that $B = \{u \mid \mu(x_0 - u) > \delta, x_0 \in \mathbb{R}^n, u \in \mathbb{R}^n\}$ for small $\delta$), then for decreasing spacing along all $n$ environmental variables:

1. The weighted average is consistent if each indicator value is the centroid of the response curve that is obtained after integration of
the corresponding response surface over the remaining \( n - 1 \) dimensions, and
the integrals, defined in Section 3, of the "marginal" response curve exist.

(2) The weighted average has asymptotically unit efficiency with respect
to maximum likelihood if the response surfaces are the multivariate extension
of (5.2), namely

\[
f(\mu_k(x_1, x_2, \ldots, x_n)) = a - \frac{1}{2}\left\{ \frac{(x_1 - u_{k1})^2}{t_i^2} + \frac{(x_2 - u_{k2})^2}{t_j^2} + \ldots + \frac{(x_n - u_{kn})^2}{t_n^2} \right\}, \tag{8.1}
\]

where \( x_1, x_2, \ldots, x_n \) are the variables of a \( n \)-dimensional habitat space, \( u_{kj} \)
and \( t_j \) are the optimum and tolerance of the \( k \)-th species with respect to \( x_j \),
and \( f(\cdot) \) is as in Section 5. [With maximum likelihood based on (8.1) the
values of \( x_1, x_2, \ldots, x_n \) at the site are estimated jointly.]

The first assertion can easily be verified. The second assertion follows from
Section 6: for fixed, but unknown values of \( x_1, x_2, \ldots, x_n \) the species have
different maxima with respect to \( x_i \), but can be divided into sets of species
with equal maxima because of the regular spacing in multidimensional
habitat space.

Weighted averaging ignores species that are absent, whereas the maximum
likelihood method uses the response curves of all species. In maximum
likelihood, absent species do potentially provide information on the environ­
ment. This paper shows that this information is negligible under the (multi­
dimensional) species packing model. Another, more informal model under
which absent species do not add much information arises when the maximum
probability of occurrence is close to zero. Then, the probability of absence is
close to unity—irrespective of the value of the environmental variable—and
hence cannot strongly influence the likelihood (see also Figure 2). The
probability of occurrence of a species, given the value of a factor, will be
small in practice for most species, just because in most sites with that value
the species will be absent due to other, unfavorable factors (cf. the effect of
neglecting other variables in a multidimensional species packing model).
Absences therefore often indicate little.

Weighted averaging is central to the algorithm of the ordination technique
known as reciprocal averaging or correspondence analysis. Reciprocal aver­
ing is commonly used in ecological ordination studies to analyse data on
the incidence or abundance of species in samples [9]. The first few ordination
axes are often interpreted as latent variables and are presumed to relate to
underlying habitat variables. The results of this paper can be extended to
provide a theoretical basis of the model that is implicitly invoked when
reciprocal averaging is used. Under the conditions of the species packing
model it can be shown that reciprocal averaging approximates the maximum likelihood solution of Gaussian-like response models in one latent variable. The stochastic model of Section 7 is an explicit formulation of the model that is used by Hill and Gauch [10] to scale the axes of (detrended) correspondence analysis.

APPENDIX

Proof of (5.1). We prove that
\[ \frac{\left[ \int \mu(x) \, dx \right]^2}{\int x^2 v(x) \, dx \cdot \int \{ [\mu'(x)]^2 / v(x) \} \, dx} \leq 1 \]  
(A1)

with equality iff \( \mu'(x) = -xv(x)/t^2 \). The left hand side in (A1) is the asymptotic \((d \rightarrow 0)\) efficiency \(v_{ML}/v_{WA}\), because summations in (3.3) and (4.2) approach integrals for \(d \rightarrow 0\), and after translation, \(x_0 = 0\). We use the Cauchy-Schwartz inequality
\[ \left[ \int p(x) q(x) \, dx \right]^2 \leq \int p^2(x) \, dx \int q^2(x) \, dx \]  
(A2)

for arbitrary functions \(p(x)\) and \(q(x) \in L^2(-\infty, \infty)\). Equality in (A2) holds iff \( p(x) = c q(x) \) with \(c\) a constant. By setting
\[ p(x) = x\sqrt{v(x)} \quad \text{and} \quad q(x) = \frac{\mu'(x)}{\sqrt{v(x)}} \]  
(A3)

and assuming that \(x \mu(x) \rightarrow 0\) for \(x \rightarrow \pm \infty\), so that
\[ \int x \mu'(x) \, dx = -\int \mu(x) \, dx, \]  
(A4)

we obtain (A1) with equality iff \(xv(x) = c\mu'(x)\), from which (5.1) follows with \(c = -t^2\). The condition \(c < 0\) arises from the assumption above (A4).

Outline proof of (7.1). Expectations and (co)variances are required of \(R = \sum_k Y_k\) and \(T = \sum_k Y_k u_k\). These are calculated by dividing the real line into small intervals with midpoints \(u_{(i)}\) \( (i = \ldots, -2, -1, 0, 1, 2, \ldots) \) and width \(\Delta\). The expectations correspond to the formulae in Section 3 with \(\mu(u)\) replaced by \(\lambda E_\lambda M(u)\); hence \(\hat{X}_{WA}\) is consistent if \(h(x)\) is constant. We show the derivation of the variances for \(x_0 = 0\) and \(h(x) = 1\). Repeated use is made of the decomposition of the variance as the sum of two components: (a) the
average conditional variance, and (b) the variance of the conditional average [18, Equation (2b.3.6), p. 97]. Species with indicator values that lie in the $i$th interval contribute to $\text{var}(R)$ an amount

$$c_i = \lambda \Delta \left[ E_S \left\{ V(u_{(i)}) \right\} + \text{var}_S \left\{ M(u_{(i)}) \right\} + E_S^2 \left\{ M(u_{(i)}) \right\} \right], \quad (A5)$$

and to $\text{var}(T)$ an amount $u_{(i)}^2 c_i$. The last two terms in (A5) can be combined to give $E\{ M^2(u_{(i)}) \}$. The total variance can be obtained by summing over all intervals, because the data from different intervals are independent, due to the properties of the Poisson process. Replacing sums by integrals gives, with $g(u) = E_S \{ V(u) + M^2(u) \}$,

$$\text{var}(R) = \lambda \int g(u) \, du,$$

$$\text{var}(T) = \lambda \int u^2 g(u) \, du,$$

$$\text{cov}(R, T) = \lambda \int u g(u) \, du. \quad (A6)$$

Because $u^2 M(u)$ and $u^2 V(u) \in L^1(-\infty, \infty)$, we have $\text{var}(T/\lambda)$, $\text{var}(R/\lambda)$, and $\text{cov}(R/\lambda, T/\lambda) \rightarrow 0$ for $\lambda \rightarrow \infty$; this and Taylor expansion of $T/R$ [11, Equation (10.17), p. 247] yield (7.1).

**Outline proof of (7.2).** Let $\hat{x}$ denote the maximum likelihood estimator, $D_y$ the first $x$ derivative of the log likelihood (4.1) evaluated at $y$, and $I$ the total information evaluated at $x_0$. Without confusion, the symbol $x$ will now be used for $x_0$. A first order Taylor expansion of $D_x$ in $x_0$ gives [4, Chapter 9.2, Equation (19)]

$$D_x = D_\hat{x} - (\hat{x} - x) I. \quad (A7)$$

Equating (A7) to zero, as in (4.1), and solving for $\hat{x} - x$ shows that, asymptotically ($\lambda \rightarrow \infty$),

$$\text{var}(\hat{x}) = \frac{\text{var}(D_x)}{I^2}. \quad (A8)$$

Conditionally on $S$ and $P$, the expectation of $D_x$ is equal to zero and its variance is the inverse of (4.2). Unconditionally, the variance of $D_x$ is therefore equal to the quantity between square brackets in (7.2). The total information is the expectation over $S$ and $P$ of the conditional information.
This expectation is equal to the variance of $D_i$; hence, from (A8) we obtain (7.2).

We would like to thank Drs. I. C. Prentice, M. O. Hill, and J. A. Hoekstra for valuable comments. Drs. T. A. B. Snijders and M. J. M. Jansen contributed to Section 3.
